Static-Priority Scheduling and Resource Hold Times

Marko Bertogna  Nathan Fisher  Sanjoy Baruah

Abstract

The duration of time for which each application locks each shared resource is critically important in composing multiple independently-developed applications upon a shared “open” platform. In a companion paper [13], we formally defined and studied the concept of resource hold time (RHT) — the largest length of time that may elapse between the instant that an application system locks a resource and the instant that it subsequently releases the resource. [13] focused exclusively upon systems scheduled using EDF; in this paper, we extend the discussion and results from [13] to systems scheduled using static-priority scheduling algorithms. We present an algorithm for computing resource hold times for every resource in an application that is scheduled using static-priority scheduling, with resource access arbitrated using the Stack Resource Policy (SRP), or the Priority Ceiling Protocol (PCP). We also present an algorithm for decreasing the RHT’s without changing the semantics of the application or compromising application feasibility.

Keywords: Resource-sharing systems; Sporadic tasks; Static-Priority Systems; Stack Resource Policy; Priority Ceiling Protocol; Resource holding times.

1 Introduction

In this paper, we study real-time systems that can be modelled as collections of sporadic tasks [23, 5], and are implemented upon a platform comprised of a single preemptive processor, and additional non-preemptable serially reusable resources. We assume that the shared resources are accessed within (possibly nested) critical sections which are guarded by semaphores, that the system is scheduled using a static-priority scheduling algorithm, such as the deadline-monotonic or rate-monotonic algorithm (e.g. see [1, 2, 17, 16, 15]), and that access to the shared resource is arbitrated by the Stack Resource Policy (SRP) [3] or the Priority Ceiling Protocol (PCP) [28].

Given the specifications of such a system, our objective is to determine, for each non-preemptable serially reusable resource, the length of the longest interval of time for which the resource may be locked. That is, we wish to determine, for each resource, the maximum amount of time that may elapse between the instant that the resource is locked, and the instant that it is next released.

Motivation and Significance. There has recently been much interest in the design and implementation of open environments [10] for real-time applications. Such open environments allow for multiple independently developed and validated real-time applications to co-execute upon a single shared platform.

While a large body of work has studied scheduling issues in such open/hierarchical real-time systems, to our knowledge all of this work has focused primarily upon the scheduling of the (fully preemptive) processor. The few papers we could find [8, 9, 11] that do address the sharing of additional shared non-preemptable resources place severe restrictions on the individual applications – in effect requiring that the resource-requesting jobs comprising these applications be made available in a first-come first-serve manner to the higher-level scheduler (as would happen, e.g., if the applications were scheduled using table-driven scheduling).

The research reported here arose out of our ongoing efforts at building an open environment that offers support for sharing non-preemptable resources in addition to a preemptive processor. Clearly, a high-level scheduler that arbitrates access to such non-preemptable shared resources among different applications must have knowledge of how long each individual application may hold each resource. Hence we find it necessary to characterize the application-wide (as opposed to task- or job-specific) usage of these resources. Specifically, we wish to be able to determine separately, for each individual application and each shared resource, the maximum amount of time for which the application may hold the shared resource. This notion is encapsulated here in the concept of resource holding times (RHT’s).

Contributions in this paper. Resource holding times (RHT’s) quantify the largest amount of time for which an individual application may keep a resource locked. In a
companion paper [13], we formally defined and studied RHT’s for EDF-scheduled applications using SRP. In this paper, we continue our study of RHT’s by deriving an algorithm for computing such resource holding times from application system specifications for SRP under static-priority scheduling, and informally describe how this algorithm may be modified when PCP rather than SRP is used. We also present, and prove correct, an algorithm for modifying a given application to obtain a semantically equivalent application that will have decreased RHT’s under SRP.

Organization. The remainder of this paper is organized as follows. In Section 2, we briefly describe our perspective on open environments in order to provide a context within which the contributions of this paper should be viewed. In Section 3, we present the formal model for resource-sharing sporadic task systems that is used in the remainder of this paper and summarize prior results on feasibility analysis of such resource-sharing sporadic task systems. Recall that our focus here is on resource holding times (RHT’s); in Section 4, we describe how these RHT’s may be computed from a given system’s specifications. In Section 5, we present, and prove properties of, an algorithm for modifying a given resource-sharing sporadic task system in such a manner that its semantics do not change but its RHT’s tend to decrease. Finally, in Section 6, we briefly describe why we are unable to reduce RHT’s using this scheme for PCP and discuss an approach to calculating the RHT’s for PCP.

2 Open environments

Most prior research on open environments has tended to focus on sharing only a preemptive processor among the applications. Hence, the proposed interfaces have been concerned with specifying the processor-specific aspects of the application, specifically, a model for its computational requirements, and a description of the scheduling algorithm used. Deng and Liu [10], Feng and Mok [22, 12], Saewong et al. [26], Shin and Lee [29], and Lipari and Bini [18] all model individual applications as collection of implicit-deadline periodic (“Liu and Layland”) tasks [21]; some of these papers assume rate-monotonic local scheduling and the others assume EDF local scheduling. The Bandwidth Sharing Server [19, 20] has a more general workload model in that it specifies for each application the speed or computational capacity of a processor upon which the application is guaranteed to meet all deadlines, if executing in isolation, using EDF as the local scheduling algorithm.

Our perspective of an open system is somewhat more general, since we allow that non-preemptable serially reusable resources may be shared among the applications in addition to the preemptive processor. Hence we will model each individual application as a collection of sporadic tasks [23], each of which generates a potentially infinite sequence of jobs. Each such job may access the shared non-preemptive serially reusable resources within (possibly nested) critical sections guarded by semaphores. An open environment will validate that such an application meets all its timing constraints when implemented in isolation upon a dedicated “virtual” processor (VP) of a particular computing capacity, when scheduled using the preemptive static-priority scheduling algorithm, such as rate-monotonic (RM) [21] or deadline-monotonic (DM) [2], and with access to the shared resources being arbitrated using the Stack Resource Policy [3] (SRP) or the Priority Ceiling Protocol [28] (PCP). (Such validation, which is performed off-line prior to actual implementation, can be done using known techniques from real-time scheduling theory, such as those in [25, 15, 16].) If the system does indeed meet all its timing constraints, we will compute the resource hold times (RHT’s) – the maximum length of time for which a resource is kept locked – for each shared resource. The computation of these resource hold times is the subject of the current paper. Provided with knowledge of the computing capacity of the VP, the resource holding times for all shared resources, and some additional information, an open environment can be designed to ensure that, if this application is admitted, then it will continue to meet all its timing constraints. A detailed and formal description of the design of such an open environment will be the subject of a future paper.

3 System model and prior results

For the purposes of this paper, we assume that the application system, denoted by \( \tau \), can be modelled as a collection of \( n \) sporadic tasks \( \tau_1, \tau_2, \ldots, \tau_n \). Each sporadic task \( \tau_i \) \((1 \leq i \leq n)\) is characterized by a worst-case execution time (WCET) \( C_i \); a relative deadline parameter \( D_i \); a
period/minimum inter-arrival separation parameter $T_i$; and its resource requirements (discussed below). Each such task generates an infinite sequence of jobs, each with execution requirement at most $C_i$ and deadline $D_i$ time-units after its arrival, with the first job arriving at any time and subsequent successive arrivals separated by at least $T_i$ time units. For the purpose of this paper, we assume that each task has $T_i \leq D_i$. Furthermore, we assume that WCET parameters are normalized with respect to the speed of the dedicated processor, i.e., each job of $\tau_i$ needs to execute for at most $C_i$ time units upon the available dedicated processor.

We also assume that the task’s are indexed in the decreasing priority order assigned by the given static-priority scheduling algorithm (i.e., if $0 < i < j \leq n$, then $\tau_i$ has higher priority than $\tau_j$). For example, a static-priority algorithm such as DM assigns a priority to each task proportional to the inverse of task’s relative deadline; in other words, for $\tau_i$ and $\tau_j$, if $D_i > D_k$ then the priority $\tau_k$ is greater than $\tau_i$.

The application is assumed to execute upon a platform comprised of a single dedicated preemptive processor, and $m$ other non-preemptible serially reusable resources $R_1, R_2, \ldots, R_m$. The resource requirements of the sporadic tasks may be specified in many ways (see, e.g., [3, 19, 24]); for our purposes, we will let

(i) $S_{ij}$ denote the length (in terms of WCET) of the largest critical section in $\tau_i$ that holds resource $R_j$; and

(ii) $C_{ik}$ denote the length (in terms of WCET) of the largest critical section in $\tau_i$ that holds some resource that is also needed by $\tau_k$’s jobs ($i \neq k$).

We will indicate with $S_j$ the largest critical section holding resource $R_j$ among all task, i.e. $S_j = \max_{\tau_i \in \tau} \{S_{ij}\}$.

For any sporadic task $\tau_i$ and any non-negative number $t$, the request bound function $RBF(\tau_i, t)$ denotes the maximum cumulative execution requests that could be generated by jobs of $\tau_i$ that have both their arrival-times within a contiguous time-interval of length $t$. It has been shown (e.g., see [15]) for sporadic task $\tau_i$ that the request bound function is:

$$RBF(\tau_i, t) \triangleq \left\lfloor \frac{t}{T_i} \right\rfloor C_i$$  \hspace{1cm} (1)

The cumulative execution request of all tasks with priority greater than $\tau_i$ and one job of $\tau_i$ over any interval of length $t$ is given by:

$$W_i(t) \triangleq C_i + \sum_{j=1}^{i-1} RBF(\tau_j, t)$$  \hspace{1cm} (2)

**Static-Priority Scheduling + SRP.** In the remainder of this paper, reasonable familiarity with the Stack Resource Policy (SRP) [3] is assumed. When it is used in conjunction with a static-priority scheduling algorithm, the rules used by the SRP to determine execution rights are summarized in Figure 1. Our focus in this paper is on SRP; therefore, due to space constraints, we will not present the entire rules for the Priority Ceiling Protocol (PCP) [28]. Section 6 will informally discuss how the techniques of this paper relate to PCP.

**Feasibility analysis**

We now review the feasibility analysis of systems that are scheduled using static-priority scheduling and SRP. A priority inversion is said to occur during run-time if the highest-priority job that is active – awaiting execution – at that time cannot execute because some resource needed for its execution is held by some other job. These lower-priority jobs are said to be the blocking jobs, and they block the higher-priority job. The higher-priority job is said to be blocked during the time that it is pending but does not execute, while lower-priority jobs execute.

It has been shown [3] that no job can be blocked after it has started executing and any job is blocked for at most one (outermost) critical section of a lower-priority task. Therefore, the maximum length of time that $\tau_i$ may be blocked by a lower-priority job is:

$$B_i \triangleq \max \{ C_{ki} | (\tau_k \in \tau) \land (k > i) \}$$  \hspace{1cm} (3)

Combining the above blocking term with the feasibility analysis of Lehoczky et al. [15], we can obtain the following result.

**Theorem 1** A task system $\tau$ is schedulable with a particular static-priority assignment and resource access arbitrated by SRP if and only if for all $\tau_i \in \tau$, there exists $t \in (0, T_i]$ such that

$$W_i(t) + B_i \leq t$$  \hspace{1cm} (4)

The above inequality does not need to be evaluated at every $t \in (0, T_i]$. Bini et al. [6] show that to determine whether $\tau_i$ is schedulable according to the static-priority assignment and SRP, it is sufficient to evaluate Inequality (4) at the following set of points:

$$TS(\tau_i) \triangleq \mathcal{P}_{i-1}(D_i)$$  \hspace{1cm} (5)

where $\mathcal{P}_i(t)$ is defined by the following recurrent expression:

$$\begin{cases} \mathcal{P}_0(t) = \{t\} \\ \mathcal{P}_i(t) = \mathcal{P}_{i-1} \left( \left\lfloor \frac{t}{T_i} \right\rfloor T_i \right) \cup \mathcal{P}_{i-1}(t) \end{cases}$$

The above set $TS(\tau_i)$ is referred to as the testing set for task $\tau_i$. The size of $TS(\tau_i)$ is pseudo-polynomial in
the parameters of the task system $\tau$ [6]. In the remainder of the paper we will assume that testing set $TS(\tau_i)$ from Equation (5) is used, and that its elements $r_1, r_2, r_3, \ldots$ are indexed according to increasing value (i.e. $r_j < r_{j+1}$ for all $j$). It can be shown that the above schedulability analysis is identical for PCP [28]).

4 Computing the resource hold times

In this section, we describe how RHT’s may be computed for each resource in a given feasible resource-sharing sporadic task system under static-priority scheduling and SRP. That is, we assume that the input task system has been deemed feasible (e.g., by the feasibility-testing algorithm described in the preceding section), and describe how we may compute RHT’s for this system.

For any resource $R_j$ and any task $\tau_i$, let $\text{RHT}(R_j, \tau_i)$ denote the maximum length of time for which $\tau_i$ may keep resource $R_j$ locked. Let $\text{RHT}(R_j)$ denote the system-wide resource holding time of $R_j$: $\text{RHT}(R_j) = \max_{\tau_i \in \tau_j} \{\text{RHT}(R_j, \tau_i)\}$. Our objective is to compute $\text{RHT}(R_j)$ for each $R_j$.

Computing $\text{RHT}(R_j, \tau_i)$. We first describe how we would compute $\text{RHT}(R_j, \tau_i)$ for a given resource $R_j$ and a given $\tau_i$ which uses $R_j$.

1. The first step is to identify the longest (in terms of WCET) critical section of $\tau_i$ accessing $R_j$. Recall that $S_{ij}$ denotes the length of this longest critical section.

2. It follows from the definition of the static-priority scheduling and SRP protocol that no task with index $\geq \Pi(R_j)$ may execute while $R_j$ is locked. Hence the only jobs that may execute while $\tau_i$ holds the lock on $R_j$ are those generated by tasks $\tau_1, \ldots, \tau_{\Pi(R_j)}-1$.

3. We now consider the number of times that a task with priority greater than $\Pi(R_j)$ may preempt $\tau_i$ while $R_j$ is locked. Suppose $\tau_i$ holds $R_j$ at most $t$. While $\tau_i$ is holding the resource, it could be preempted by a task $\tau_t \in \{\tau_1, \ldots, \tau_{\Pi(R_j)}\}$ for at most:

$$RBF(\tau_t, t)$$

(6)

Also, observe that if $\tau_i$ acquires $R_j$ at time $t_{ij}$, then at time $t_{ij}$ there are no active jobs of tasks $\tau_1, \ldots, \tau_{\Pi(R_j)}-1$ (otherwise, $\tau_i$ could not execute at time $t_{ij}$). So, the cumulative execution requests of jobs $\{\tau_1, \ldots, \tau_{\Pi(R_j)}-1\}$ that can preempt $\tau_i$ while it is holding resource $R_j$ for $t$ units of time, along with maximum amount $\tau_i$ can execute on resource $R_j$ is given by:

$$W^{(j)}_i(t) = S_{ij} + \sum_{t=1}^{\Pi(R_j)-1} RBF(\tau_t, t).$$

(7)

4. Let $t^*_i$ be the smallest fixed point of function $W^{(j)}_i(t)$ (i.e. $W^{(j)}_i(t^*_i) = t^*_i$). Using techniques from [14, 15], we can obtain $t^*_i$ in time complexity that is pseudo-polynomial in the parameters of $\{\tau_1, \ldots, \tau_{\Pi(R_j)}-1\} \cup \{\tau_i\}$. $t^*_i$ is the maximum amount of time $\tau_i$ can hold resource $R_j$. Thus,

$$\text{RHT}(R_j, \tau_i) = t^*_i.$$  

(8)

It turns out that in order to find $\text{RHT}(R_j, \tau_i)$ we do not need to evaluate $\text{RHT}(R_j, \tau_i)$ for every $\tau_i$ that accesses resource $R_j$. Let $\tau^{(j)}_{\text{max}} = \arg \max_{\tau_i \in \tau_j} (S_{ij})$, that is, $\tau^{(j)}_{\text{max}}$ is the task with the largest critical section (in terms of WCET) that holds resource $R_j$. The following theorem shows that we only need to calculate $\text{RHT}(R_j, \tau^{(j)}_{\text{max}})$ to determine $\text{RHT}(R_j)$.

Theorem 2 $\text{RHT}(R_j)$ equals $\text{RHT}(R_j, \tau^{(j)}_{\text{max}})$.

Proof: Rewriting Equation (7) for a tasks $\tau_k$ that access resource $R_j$, we have

$$W^{(j)}_k(t) = S_{kj} + \sum_{t=1}^{\Pi(R_j)-1} RBF(\tau_t, t).$$  

(9)

Since Equations (7) and (9) differ only by the $S_{ij}$ and $S_{kj}$ terms (i.e. the sum of the $RBF(\tau_t, t)$ terms in the equations is independent of tasks $\tau_i$ and $\tau_k$), the smallest fixed point of Equation (7) exceeds or equals the smallest fixed point of Equation (9) if and only if $S_{ij} \geq S_{kj}$. Therefore, $S_{ij} \geq S_{kj}$ implies $\text{RHT}(R_j, \tau_i) \geq \text{RHT}(R_j, \tau_k)$. Since $\tau^{(j)}_{\text{max}}$ has the largest critical section of length $S_j$ holding $R_j$ among all tasks in terms of WCET, it also has the largest total holding time of $R_j$. Therefore, $\text{RHT}(R_j, \tau^{(j)}_{\text{max}}) \geq \text{RHT}(R_j, \tau_i), \forall \tau_i$ and the theorem follows.

5 Minimizing the resource hold times

In the previous section we computed the resource holding times for systems scheduled with static priority that use SRP to arbitrate the access to resources; in this section, we address the issue of decreasing these RHT’s, adapting the result we obtained in [13] for EDF to the static-priority systems considered in this paper. Since our objective is to apply the results obtained here for implementing open real-time environments that allow for resource-sharing, reducing the
RHT’s will be beneficial to decrease the “interference” between different applications executing upon a common platform. (In the extreme, if all the RHT’s were equal to zero then the open environment could ignore resource-sharing entirely.)

The algorithm we present in this section maintains the schedulability properties of SRP (an example of a maintained property, is the optimality of DM+SRP under certain assumptions [7]), while reducing resource holding times if possible. That is, we attempt to modify a given resource-sharing sporadic task system such that its semantics do not change, but the resource holding times in the resulting system are smaller (or in any event, no larger) than in the original. Furthermore, the modified system is scheduled by the exact same scheduling protocol as the original system; i.e., we are proposing no changes to the application semantics, nor to the scheduling algorithm deployed.

In [27], a similar technique to the one presented in the next subsection is used to decrease the number of preemptions in a static priority system with no critical sections. We improve that technique using a more general task model, reducing the overall complexity of the algorithm and taking into consideration the access to exclusive resources.

5.1 Reducing RHT for a single resource

In this section, we derive an algorithm for modifying a given resource-sharing sporadic task system such that the resource holding time \(RHT(R_j)\) is reduced, for a single resource \(R_j\). In Section 5.2, we extend this algorithm to reduce RHT’s for all the shared resources in the system. We will first informally motivate and explain the intuition behind our algorithm; a more formal treatment follows.

Suppose that task \(τ_i\) uses resource \(R_j\). We saw (in Section 4 above) that \(τ_i\)’s execution on \(R_j\) may only be interrupted by jobs of tasks with index strictly less than \(Π(R_j)\). Hence the smaller this preemption ceiling \(Π(R_j)\), the smaller the value of \(RHT(R_j, τ_i)\); in the extreme, \(Π(R_j) = 1\) and \(RHT(R_j, τ_i) = S_{ij}\) (i.e., the critical section executes without preemption). Hence, our RHT minimization strategy aims to make \(Π(R_j)\) of each resource \(R_j\) as small as possible without rendering the system infeasible. Let us consider a particular resource \(R_j\) with \(Π(R_j) > 1\) to illustrate our strategy (if \(Π(R_j) = 1\), then \(R_j\)’s preemption ceiling cannot be reduced any further). We follow the same approach as in [13]:

We add a “dummy” critical section — one of zero WCET — that accesses \(R_j\) to the task \(τ_{Π(R_j)−1}\), and check the resulting system for feasibility. If the resulting system is infeasible, then we remove the critical section: we are unable to reduce \(RHT(R_j, τ_i)\).

Observe that adding such a critical section effectively decreases the preemption ceiling of \(R_j\) by one. Hence, the \(RHT(R_j, τ_i)\) in the resulting system is no larger than in the original system.

Observe also that adding such a critical section with zero WCET is a purely syntactic change; hence, this change has no semantic effect on the task system.

By repeatedly applying the above strategy until it cannot be applied any further, we will have reduced each resource’s preemption ceiling to the smallest possible value, thereby reducing the RHT’s as much as possible using this strategy.

Having provided an informal description above, we now proceed in a more formal fashion by providing the necessary technical details. Let us begin with some assumptions: Our algorithm assumes that the schedulability of the initial system has been verified. We will also assume that the initial schedulability test for each task \(τ_i\) evaluates Inequality 4 for each \(r_k \in TS(τ_i)\) in increasing order. If Inequality 4 is not satisfied for \(r_k\), the \(r_k\) is removed from \(TS(τ_i)\); otherwise, if Inequality 4 is satisfied the schedulability test for \(τ_i\) terminates and the “reduced-size” \(TS(τ_i)\) is returned. Therefore, \(r_1\) (the first element) of each modified testing set \(TS(τ_i)\) is guaranteed to satisfy Inequality 4.

The pseudo-code for reducing \(R_j\)’s preemption ceiling to the minimum possible value is given in Figure 2, as Procedure \(\text{MINCEILING}(R_j)\). We will now argue that Procedure \(\text{MINCEILING}(R_j)\) is correct.

---

Figure 2. Reducing the preemption ceilings for \(R_j\).
We show that each iteration of the while loop (Line 1) maintains system schedulability: suppose that we are attempting to decrease the ceiling \( \Pi(R_j) \) of a resource \( R_j \) from its current value \( i + 1 \) to \( i \). Observe this change would only affect the blocking term \( B_i \) for task \( \tau_i \): higher-priority tasks than \( \tau_i \) cannot be blocked by a task accessing resource \( R_j \), and tasks with priority lower than \( \tau_i \) have already calculated the maximum blocking due to a task that accesses \( R_j \). In fact, if we decrease \( \Pi(R_j) \) to \( i \), \( B_i \) would change as follows:

\[
B_i \leftarrow \max(B_i, S_j)
\]

(10)

To prove that Procedure MINCEILING(\( R_j \)) maintains schedulability, we must prove the following theorem:

**Theorem 3** During a single iteration of the while loop (Line 1) of Procedure MINCEILING(\( R_j \)), \( \Pi(R_j) \) is reduced by one if and only if \( \tau_i \) is schedulable with \( B_i \) updated according to Equation 10.

Before we prove this theorem, we prove the following useful lemma concerning updates of the testing set \( TS(\tau_i) \) by Procedure MINCEILING(\( R_j \)):

**Lemma 1** Prior to each iteration of the while loop (Line 1) of Procedure MINCEILING(\( R_j \)), the minimum element of \( TS(\tau_i) \) satisfies Inequality 4 for all \( \tau_i \in \tau \).

**Proof Sketch:** The proof is by induction. Assume that the lemma holds prior iteration of the while loop. Now consider a loop where \( \Pi(R_j) \) is currently \( i + 1 \). Obviously, only \( \tau_i \) can be affected by the update of Line 6. So, we only need to prove that Inequality 4 holds for the first test point of \( TS(\tau_i) \) after completion of the loop.

The for loop considers test points of \( TS(\tau_i) \) in increasing order. Let \( B_i^{\text{old}} \) be the blocking term for \( \tau_i \), prior when \( \Pi(R_j) = i + 1 \); \( B_i^{\text{new}} \) is the blocking term if \( \Pi(R_j) = i \) (calculated by Equation 10). Consider the first test point \( r_1 \) in the current \( TS(\tau_i) \). By induction hypothesis, Inequality 4 is satisfied at \( r_1 \) with \( B_i^{\text{old}} \). If \( S_j \leq B_i^{\text{old}} \), then Inequality 4 will be trivially satisfied at \( r_1 \), and the lemma will be true.

So, we will assume that \( S_j > B_i^{\text{old}} \) (i.e. \( S_j \) equals \( B_i^{\text{new}} \)). Again consider the first test point \( r_1 \). If the condition of Line 3 for \( r_1 \) is violated, then Inequality 4 is also false, and Line 6 is executed, removing the first test point. The removal of successive test points is repeated until the condition of Line 3 is satisfied. When the condition of Line 3 is finally satisfied, \( \Pi(R_j) \) is updated to \( i \), and Inequality 4 is satisfied with the new blocking term. Otherwise, if there are no more elements, \( TS(\tau_i) \) is empty. In either case, the lemma continues to hold.

We are now prepared to prove Theorem 3:

**Proof of Theorem 3** Again, observe that only the schedulability of \( \tau_{\Pi(R_j)-1} \) is affected by the iteration of the while loop of MINCEILING(\( R_j \)). Let \( \Pi(R_j) \) be equal to \( i + 1 \) prior to the considered iteration.

We will prove the “only if” part of the theorem first. Assume that \( \tau_i \) is not schedulable after the update of \( \Pi(R_j) \) to \( i \) (and update of \( B_i \) according to Equation 10). By Theorem 1, there does not exist an element of \( TS(\tau_i) \) that satisfies Inequality 4 with the updated \( B_i \). \( \Pi(R_j) \) will not be reduced.

Next, we will prove the “if” portion of the theorem. Assume that \( \tau_i \) is schedulable according to Theorem 1 if \( \Pi(R_j) \) is updated to \( i \). Again, let \( B_i^{\text{old}} \) and \( B_i^{\text{new}} \) denote the same values as Lemma 1. So, there exists a \( t \in (0, D_i] \) such that Inequality 4 is satisfied with \( B_i^{\text{new}} \). If \( S_j \leq B_i^{\text{old}} \), then \( B_i^{\text{old}} = B_i^{\text{new}} \). By Lemma 1, the smallest value of the current \( TS(\tau_i) \) satisfies Inequality 4; thus, the condition of Line 3 is satisfied, and \( \Pi(R_j) \) is reduced to \( i \). Now, assume that \( S_j > B_i^{\text{old}} \) (i.e. \( B_i^{\text{new}} \) equals \( S_j \)). Since in this section we minimize only one resource ceiling, we know that prior to the first for iteration, \( TS(\tau_i) \) has only been reduced by the initial schedulability test. Then, using Lemma 1, we know that \( \tau_i \) satisfies Inequality 4 with blocking term \( B_i^{\text{old}} \), and all points removed from the initial testing set failed the same Inequality. Being \( B_i^{\text{new}} > B_i^{\text{old}} \), we know that the removed points would also fail the test using \( B_i^{\text{new}} \) as blocking term. Therefore, we could safely check the condition of Line 3 starting from \( r_1 \), and MINCEILING will eventually update \( \Pi(R_j) \).

**5.2 Reducing RHT’s for all resources**

In this section, we describe how the algorithms of Section 5.1 may be used to decrease the resource hold times for all the resources in a resource-sharing sporadic task system. The next result gives an algorithm to minimize each resource ceiling in an “optimal” way. We will say that a minimizing strategy is optimal if each \( \Pi(R_i) \) obtained with this strategy will be equal to the lowest possible ceiling that could safely be assigned to \( R_i \) in the original task set (i.e. when no other ceiling has been modified).

**Theorem 4** Calling MINCEILING(\( R_i \)) for every resource in order according to their \( S_j \) value (i.e. for every \( R_j \), \( R_k \), if \( S_j < S_k \) then \( R_j \)’s ceiling is minimized before \( R_k \)’s) is an optimal minimizing strategy.

**Proof:** We begin by ordering the resources according to their \( S_j \) value (i.e. for every \( R_j \) and \( R_k \) in \( \{R_1, R_2, \ldots, R_m\} \), if \( j < k \) then \( S_j < S_k \)). We have to prove that calling MINCEILING(\( R_i \)) starting from \( R_1 \) and systematically proceeding in the given order, every time there is an element in the initial testing set that satisfies Condition 4 when it is evaluated to check if a resource ceiling could be decreased by one, then there exists an element
in the corresponding reduced set satisfying the same condition.

To see this, note that when $\text{MINCEILING}(R_i)$ is called to decrease $\Pi(R_i)$, the condition at Line 3 is evaluated for every point of the corresponding reduced testing set, which is equal to the initial set excluding the elements that failed a similar condition during a previous call to $\text{MINCEILING}(R_k)$. Since the removed points failed Condition 4 with $S_k$, then they would also fail Condition 4 with a higher value $S_j$.

The pseudo-code of procedure $\text{REDUCEALL}(\tau)$ in Figure 3 makes repeated calls to $\text{MINCEILING}(R_j)$ in the order given by Theorem 4.

### 5.3 Computational Complexity

As can be seen from the pseudo-code in Figure 2, to decrease the ceiling of a resource $R_j$ by 1 to $i$, Condition (4) must potentially be re-evaluated for every element in the testing set $TS(\tau_j)$. There are potentially pseudo-polynomially many such elements; hence, the computational complexity of reducing the preemption ceiling of a single resource by 1 is pseudo-polynomial in the representation of the task system. For a resource that had an initial ceiling equal to $n$, that can be reduced to 1, Condition (4) has to be tested for $(n - 1)$ different tasks, which remains in pseudo-polynomial time. Observe that we also avoid re-checking points that do not satisfy Condition (4). So, it is easy to see that the worst-case number of test points evaluated to minimize the ceiling of all resources is the same of the initial schedulability test.

### 6 Calculating and Minimizing RHT’s for PCP

In SRF, a task holding a resource $R_j$ executes at the priority of $\Pi(R_j)$ for the duration of the critical section for $R_j$. PCP differs by increasing the priority of a task $\tau_k$ holding $R_j$ only when a higher-priority task $\tau_i$ (with priority lower than the system ceiling) is blocked. In this case, $\tau_k$ “inherits” $\tau_i$’s priority. (The reader is referred to [28] for a detailed description of PCP). Thus, the resource-holding time of $\tau_i$ for $R_j$ is maximized when $\tau_i$ never inherits any task’s priority and may be preempted by all higher-priority tasks, i.e. when all tasks $\tau_k$ with $\Pi(R_j) \leq k < i$ do not try to enter any critical section. Without making any assumption on the location of critical sections inside the worst-case code of any task (see [4]), an upper-bound on the $\text{RHT}(R_j, \tau_i)$ for this scenario is the smallest solution $t$ satisfying:

$$S_{ij} + \sum_{t=1}^{i-1} \text{RBF}(\tau_t, t) \leq t. \quad (11)$$

$\text{RHT}(R_j) \overset{\text{def}}{=} \max_{\tau_i \in \tau} \{\text{RHT}(R_j, \tau_i)\}$. Please note that Theorem 2 does not hold for PCP.

We would also like to emphasize that the technique discussed in Section 5 does not apply to PCP. Since in the worst-case scenario a task $\tau_i$ locking a resource $R_j$ could be preempted also by tasks with priority lower than the ceiling of $R_j$, artificially lowering the ceiling will have no effect on $\text{RHT}(R_j)$. Therefore, PCP may be inappropriate to use for systems that require small RHT’s.

### 7 Conclusion

Open environments, which allow for multiple independently-developed and validated applications to co-execute concurrently upon a common platform, are currently a hot topic in real-time systems research. Thus far, however, much work has assumed that shared execution platforms are comprised of only a single preemptive processor.

We believe that the logical next step in open environment design and implementation is to extend such environments to allow for more general shared platforms, that may be comprised of non-preemptable serially-reusable resources in addition to a preemptive processor. We are currently working on designing such a “second-generation” open environment. We have discovered that these more general second-generation open environments require a characterization of the amount of time that individual applications may keep specific resources locked (thereby denying the other applications access to the locked resource). In [13], we presented a systematic and methodical study of this specific behavioral feature for dynamic-priority scheduling. In this paper, we continue our study of resource locking durations by analyzing the behavior of static-priority systems. Our contributions include the following:

- With respect to application systems that can be modelled using the resource-sharing sporadic task model, we have abstracted out what seems to be the most critical aspect of such resource locking. We have formalized this abstraction into the concept of resource hold
times (RHT’s).

- We have presented an algorithm for computing RHT’s for resource-sharing sporadic task systems scheduled using static-priorities and SRP. We have also briefly described how to obtain RHT’s for PCP.

- We have presented, and proved the optimality of, an algorithm for decreasing RHT’s of resource-sharing sporadic task systems scheduled using the static-priority scheduling and SRP.
